Abstract

The Abstract paragraph should be indented 0.25 inch (1.5 picas) on both left and right-hand margins. Use 10 point type, with a vertical spacing of 11 points. The **Abstract** heading must be centered, bold, and in point size 12. Two line spaces precede the Abstract. The Abstract must be limited to one paragraph.

1 INTRODUCTION

Recently, ML has flourished in critical domains, such as healthcare and finance. In these areas, we need ML models that predict accurately but also with the ability to explain their predictions. Therefore, Explainable AI (XAI) is a rapidly growing field due to the interest in interpreting black box machine learning (ML) models. XAI literature distinguishes between local and global interpretation methods (Molnar et al., 2020). Local methods explain a specific prediction, whereas global methods explain the entire model behavior. Global methods provide a universal explanation, summarizing the numerous local explanations into a single interpretable outcome (number or plot). For example, if a user wants to know which features are significant (feature importance) or whether a particular feature has a positive or negative effect on the output (feature effect), they should opt for a global explainability technique. Aggregating the individual explanations for producing a global one comes at a cost. In cases where feature interactions are strong, the global explanation may obfuscate heterogeneous effects (Herbinger et al., 2022) that exist under the hood, a phenomenon called aggregation bias (Mehrabi et al., 2021).

Feature effect forms a fundamental category of global explainability methods, isolating a single feature’s average impact on the output. Feature effect methods suffer from aggregation bias because the rationale behind the average

effect might be unclear. For example, a feature with zero average effect may indicate that the feature has no effect on the output or, contrarily, it has a highly positive effect in some cases and a highly negative one in others.

There are two widely-used feature effect methods; Partial Dependence Plots (PDPlots)(Friedman, 2001) and Aggregated Local Effects (ALE)(Apley and Zhu, 2020). PDPlots have been criticized for producing erroneous feature effect plots when the input features are correlated due to marginalizing over out-of-distribution synthetic instances. Therefore, ALE has been established as the state-of-the-art feature effect method since it can isolate feature effects in situations where input features are highly correlated.

However, ALE faces two crucial drawbacks. First, it does not provide a way to inform the user about potential heterogeneous effects that are hidden behind the average effect. In contrast, in the case of PDPlots, the heterogeneous effects can be spotted by exploring the Individual Conditional Expectations (ICE)(Goldstein et al., 2015). Second, ALE requires an additional step, where the axis of the feature of interest is split in K fixed-size non-overlapping intervals, where K is a hyperparameter provided by the user. This splitting is done blindly, which can lead to inconsistent explanations.

In this paper, we extend ALE with a probabilistic component for measuring the uncertainty of the global explanation. The uncertainty of the global explanation expresses how certain we are that the global (expected) explanation is valid if applied to an instance drawn at random and informs the user about the level of heterogeneous effects hidden behind the expected explanation. Our method completes ALE, as ICE plots complement PDPlots, for revealing the heterogeneous effects.

Our method also automates the step of axis splitting into non-overlapping intervals. We, firstly, transform the bin splitting step into an unsupervised clustering problem and, second, find the optimal bin splitting for a robust estimation of (a) the global (expected) effect and (b) the uncertainty of the explanation from the limited samples of the training set. We formally prove that the objective of the clustering problem has as lower-bound the aggregated uncertainty of the global explanation. Our method works out of the box

without requiring any input from the user.

Contributions. The contributions of this paper are the following:

- We introduce Uncertainty DALE (UDALE), an extension of DALE that quantifies the uncertainty of the global explanation, i.e. the level of heterogeneous effects hidden behind the global explanation.
- We provide an algorithm that automatically computes the optimal bin splitting for robustly estimating the explanatory quantities, i.e., the global effect and the uncertainty.
- We formally prove that our method finds the optimal grouping of samples, minimizing the added uncertainty over the unavoidable heterogeneity that is the lower-bound of the objective.
- We provide empirical evaluation of the method in artificial and real datasets.

The implementation of our method and the code for reproducing all the experiments is provided in the submission and will become publicly available upon acceptance.

2 BACKGROUND AND RELATED WORK

Notation. We refer to random variables (rv) using uppercase X , whereas to simple variables with plain lowercase x . Bold denotes a vector; \mathbf{x} for simple variables or \mathbf{X} for rvs. Often, we partition the input vector $\mathbf{x} \in \mathbb{R}^D$ to the feature of interest $x_s \in \mathbb{R}$ and the rest of the features $\mathbf{x}_c \in \mathbb{R}^{D-1}$. For convenience we denote it as (x_s, \mathbf{x}_c) , but we clarify that it corresponds to the vector $(x_1, \dots, x_s, \dots, x_D)$. Equivalently, we denote the corresponding rv as $X = (X_s, \mathbf{X}_c)$. The black-box function is $f : \mathbb{R}^D \rightarrow \mathbb{R}$ and the feature effect of the s -th feature is $f^{\langle \text{method} \rangle}(x_s)$, where $\langle \text{method} \rangle$ is the name of the feature effect method.¹

Feature Effect Methods. PDPlots formulate the feature effect of the s -th attribute as an expectation over the marginal distribution \mathbf{X}_c , i.e., $f^{\text{PDP}}(x_s) = \mathbb{E}_{\mathbf{X}_c}[f(x_s, \mathbf{X}_c)]$. MPlots formulate it as an expectation over the conditional $\mathbf{X}_c|X_s$, i.e., $f^{\text{MP}}(x_s) = \mathbb{E}_{\mathbf{X}_c|X_s=x_s}[f(x_s, \mathbf{X}_c)]$. ALE computes the global effect at x_s as an integration of local effects. The local effects are measured as the expected change on the output $\frac{\partial f(x_s, \mathbf{x}_c)}{\partial x_s}$ over the conditional distribution $\mathbf{X}_c|X_s$. The formula that defines ALE is presented below:

$$f^{\text{ALE}}(x_s) = c + \int_{z_{s, \min}}^{x_s} \mathbb{E}_{\mathbf{X}_c|X_s=z} \left[\frac{\partial f(z, \mathbf{X}_c)}{\partial z} \right] dz \quad (1)$$

The constant c is used for centering the ALE plot. PDPlots integrate over unrealistic instances due to the use of the marginal distribution $p(\mathcal{X}_1)$. Therefore, they incorrectly result in a quadratic effect in the region $x_1 \in [0, 1]$. MPlots resolve this issue using the conditional distribution $\mathcal{X}_2|\mathcal{X}_1$ but suffer from computing combined effects. ALE plots resolve, both they have two drawbacks TODO add more info.

TODO: Discuss the interpretation of ALE. The differences from PDP. Analyze both methods as processes.

Quantify the Heterogeneous Effects. It is crucial for feature effect methods to inform about the heterogeneous effects. Elaborate. Interpretation of the heterogeneous effects behind the global effect is available only for PDP, with three different approaches; (a) ICE and d-ICE plots provide a visual understanding of the heterogeneous effects. (b) grouping of ICE in homogeneous clusters, for splitting the input space into subspace(s) with homogeneous effects (c) Feature Interaction strength indexes, like H-statistic, provide a value indicating how much a feature interacts with the others (not the type of interaction). There is no method for quantifying the heterogeneous effects, based on ALE. Therefore, no method to exploit the advantages of ALE while, on the same time, informing about the heterogeneous effects.

Bin Splitting. ALE also has the peculiarity of splitting the axis into intervals, allocating the instances of the training set in the intervals and compute a single (constant) effect in each interval. With DALE extension, bin splitting is decoupled from instant effect estimation. With our extension for measuring the heterogeneous effects, we transform interval splitting from a step to a clustering problem with a meaningful objective to minimise. We provide a thorough analysis, where we show that our objective has a consistent meaning. It can be split in two parts; the first part is the unavoidable uncertainty due to the natural characteristics of the experiment, i.e., the data generating distribution and the black-box function. The second part is an added uncertainty due to the limited-samples estimation, that enforces to create groups with constant main effect. We opt for minimizing the objective, i.e. sum of the two uncertainties, that given that the first uncertainty is independent of the bin splitting, therefore we want to minimize the added uncertainty. To conclude, we transform the axis-splitting into an unsupervised clustering problem with a principled objective. We a computationally-grounded solution that works out-of-the-box, relaxing the user from providing a hyperparameter without any indication which one is the correct. This step can be used independently of whether the user wants to explore the heterogeneous effects or not.

¹An extensive list of all symbols used in the paper is provided in the helping material.

3 THE ... METHOD

3.1 ALE with Uncertainty Quantification

ALE defines the local effect of x_s on $f(\cdot)$ at a single point (x_s, \mathbf{x}_c) as $\frac{\partial f}{\partial x_s}(x_s, \mathbf{x}_c)$. All the local explanations at x_s are weighed by the conditional distribution $p(\mathbf{x}_c|x_s)$ and are averaged, to produce the summarized effect:

$$\mu(x_s) = \mathbb{E}_{\mathbf{x}_c|x_s} \left[\frac{\partial f}{\partial x_s}(x_s, \mathbf{x}_c) \right] \quad (2)$$

As described at the Introduction, limiting the explanation at this level does not shed light to possible heterogeneous effects behind the averaged explanation. Therefore, we model the uncertainty of the local effects at $\mathcal{H}(x_s)$ as the variance of the local explanations:

$$\mathcal{H}(x_s) := \sigma^2(x_s) = \text{Var}_{\mathbf{x}_c|x_s} \left[\frac{\partial f}{\partial x_s}(x_s, \mathbf{x}_c) \right] \quad (3)$$

The uncertainty of the explanation emerges from the natural characteristics of the experiment, i.e., the data generating distribution and the properties of the black-box function. In Section (TODO), we propose appropriate visualizations for easier interpretation of Eq. (3). In ALE, the feature effect at x_s is the accumulation of the averaged local effects from x_{min} until x_s , as show in Eq. (1). Equivalently, we define the accumulated uncertainty (variance) until the point x_s , as the integral of the variances of local effects:

$$f_{\sigma^2}^{\text{ALE}}(x_s) = \int_{z_{s,min}}^{x_s} \sigma^2(z) dz \quad (4)$$

The accumulated uncertainty is not a directly interpretable quantity. It only helps us define a sensible objective for the interval spliting step, as we discuss in Section TODO: add ref.

3.2 Uncertainty Quantification and Estimation at an Interval

In real scenarios, we have ignorance about the data-generating distribution $p(x_s, \mathbf{x}_c)$ and all estimations are based on the limited instances of the training set. Estimating Eqs. (2), (3) at the granularity of a point x_s is impossible, because the probability of observing a sample inside the interval $[x_s - h, x_s + h]$ tends to zero, when $h \rightarrow 0$. Therefore, we are obliged to split the axis of x_s into a sequence of non-overlapping intervals (bins) and estimate the mean and the variance from the samples that lie inside each bin. The mean effect at an interval $[z_1, z_2]$ is defined as the mean of the expected effects:

$$\mu(z_1, z_2) = \frac{1}{z_2 - z_1} \int_{z_1}^{z_2} \mathbb{E}_{\mathbf{x}_c|x_s=z} \left[\frac{\partial f}{\partial x_s} \right] dz \quad (5)$$

Accordingly, the accumulated variance at an interval $[z_1, z_2]$ is defined as:

$$\sigma^2(z_1, z_2) = \int_{z_1}^{z_2} \mathbb{E}_{\mathbf{x}_c|x_s=z} \left[\left(\frac{\partial f}{\partial x_s} - \mu(z_1, z_2) \right)^2 \right] dz \quad (6)$$

Eqs. (5), (6) can be directly estimated from the set \mathcal{S} of the dataset instances with the s -th feature lying inside the interval, i.e., $\mathcal{S} = \{\mathbf{x}^i : z_1 \leq x_s^i < z_2\}$. The mean effect at the interval, Eq. (5) is approximated by:

$$\hat{\mu}(z_1, z_2) = \frac{1}{|\mathcal{S}|} \sum_{i:\mathbf{x}^i \in \mathcal{S}} \left[\frac{\partial f}{\partial x_s}(\mathbf{x}^i) \right] \quad (7)$$

and the accumulated variance, Eq. (6) can be approximated by

$$\hat{\sigma}^2(z_1, z_2) = \frac{z_2 - z_1}{|\mathcal{S}|} \sum_{i:\mathbf{x}^i \in \mathcal{S}} \left(\frac{\partial f}{\partial x_s}(\mathbf{x}^i) - \hat{\mu}(z_1, z_2) \right)^2 \quad (8)$$

The approximation is unbiased only if the points are uniformly distributed in $[z_1, z_2]$. (TODOs: Check what happens otherwise).

3.3 Bin Splitting as a Clustering Problem

ALE, Eq.(1), is estimated by splitting the axis x_s into a sequence of non-overlapping bins (TODO: add some discussion for ALE, DALE):

$$\hat{f}_{\mu}^{\text{ALE}}(x_s) = \Delta x \sum_{k=1}^{k_x} \hat{\mu}(z_{k-1}, z_k) \quad (9)$$

and

$$\hat{f}_{\sigma^2}^{\text{ALE}}(x_s) = \sum_{k=1}^{k_x} \hat{\sigma}^2(z_{k-1}, z_k) \quad (10)$$

We denote as k_x the index of the bin that x_s belongs to, i.e. $k_x : z_{k_x-1} \leq x_s < z_{k_x}$ and \mathcal{S}_k is the set of training instance that lie in the k -th bin, i.e. $\mathcal{S}_k = \{\mathbf{x}^i : z_{k-1} \leq x_s^i < z_k\}$. Both methods face the limitation that the partitioning into non-overlapping intervals is done blindly. The user pass the total number of bins K as a hyperparameter, the bins are defined with equal-size splitting, and the training instances are allocated accordingly. This approach is

vulnerable to non-robust estimations. The mean effect is often poorly approximated from a very small number of samples and the mean effect of empty bins is interpolated from their neighbors. Furthermore, in our case, we need sufficient sample populations for estimating the variance of the approximation, apart from the mean effect.

3.3.1 Methodology

For overcoming this limitations, we reformulate the partitioning as a clustering of the training instances into a sequence variable-size intervals. The objective of the clustering problem is inspired

ALE requires splitting the estimation of the

In this section, we introduce a framework

Theorem 1. If we define the residual $\rho(z)$ as the difference between the expected effect at x_s and the mean expected effect at the interval, i.e $\rho(z) = \mu(z) - \mu(z_1, z_2)$, then, the accumulated variance at an interval $[z_1, z_2]$ is the accumulation of the all variances plus the accumulation of squared residuals inside the interval:

$$\sigma^2(z_1, z_2) = \int_{z_1}^{z_2} \sigma^2(z) + \rho^2(z) \partial z \quad (11)$$

The proof is at the Appendix. Theorem 1 decouples the accumulated variance at an interval, the only quantity we can estimate, into two terms. The first term $\int_{z_1}^{z_2} \sigma^2(z) \partial z$, quantifies the uncertainty due to the natural characteristics of the experiment and the second term adds extra uncertainty due to the limited resolution.

Uncertainty of the global effect. Eq. (8) gives an approximation of the uncertainty of the bin effect. The uncertainty of the global effect is simply the sum of the uncertainties in the bin effects.

Minimizing the uncertainty Solving the problem of finding (a) the optimal number of bins K and (b) the optimal bin limits for each bin $[z_{k-1}, z_k] \forall k$ to minimize:

$$\mathcal{L} = \sum_{k=0}^K \hat{\sigma}_k(z_{k-1}, z_k) \quad (12)$$

The constraints are that all bins must include more than τ points, i.e., $|\mathcal{S}_k| \geq \tau$.

TODOS. Show theoretically that $\mathcal{L} \geq \int_{x_{s,\min}}^{x_{s,\max}} \sigma^2(x_s) \partial x_s$
